Abstract: The paper contains a sensitivity analysis of the influence of uncertainties in input hydrological, morphological and operating data required for a proposal for active reservoir conservation storage capacity and its achieved values. By introducing uncertainties into the considered inputs of the water management analysis of a reservoir, the subsequent analysed reservoir storage capacity is also affected with uncertainties. The values of water outflows from the reservoir and the hydrological reliabilities are affected with uncertainties as well. A simulation model of reservoir behaviour has been compiled with this kind of calculation as stated below. The model allows evaluation of the solution results, taking uncertainties into consideration, in contributing to a reduction in the occurrence of failure or lack of water during reservoir operation in low-water and dry periods.

Keywords: Uncertainties; Reliability; Reservoir storage capacity; Monte Carlo method; Mean monthly flows; Evaporation; Elevation–volume curve; Elevation–area curve.

INTRODUCTION

The current knowledge in the field of climatology indicates a gradual change in hydroclimatic conditions all over the world. Climate changes are reflected in the changes in the hydrological cycle due to the redistribution of precipitation during the year and they contribute to more frequent occurrences of extremes in the form of floods and dry periods.

Clear signs of climatic changes have appeared in the Czech Republic in recent years. It should be noted that, from the hydroclimatical point of view, 2011 and 2012 were considered to be extremely dry (Zahradniček et al., 2014). The temperatures in the winter in 2014 were considerably above average. In that period, the water storage in snow cover was the lowest in the last twenty years. The consequences were extraordinary manipulations at some water reservoirs. It is apparent that the subject of advanced management and control of surface water resources is becoming more and more important. The manipulation rules of large open water reservoirs were approved in the period of construction of those waterworks and subsequently reviewed for the current hydrological conditions. It will be necessary to carry out a thorough review in the future in relation to their adaptability due to climate change and hydrological cyclic evolution. Therefore, the tasks of water management analysis of reservoirs for active reservoir conservation storage capacity will always be necessary and research in this field is valuable. In particular, the application of new optimization methods for water management analysis of reservoirs, new reservoir performance definitions and, last but not least, the introduction of analysis of uncertainties in these problems or combinations of the above mentioned applications and knowledge.

Under the given conditions, it is necessary to introduce input data uncertainties into the proposal for control of reservoir storage capacity. The procedures which will be described below refer to “The influence of uncertainties in the calculation of mean monthly discharges on reservoir storage” (Marton et al., 2011). This paper describes, in detail, the introduction of uncertainties in measurement in determining below average monthly flows over the stage-discharge curve in a river and a number of measurements of hourly records of river stages in a hydrometric profile. For this sort of computation, the Monte Carlo method was used. One of the results was creating the random time series of mean monthly flows, which was affected by uncertainties of measurement in the hydrometric profile. The random series of mean monthly flows served as input data for the water management analysis of the reservoir storage capacity, when the spectrum of reservoir storage volumes for the maximum hydrological reliability of 100% were determined repeatedly using single-pass simulations of reservoir operation. The final spectrum of random reservoir storage capacities was evaluated statistically and the interval of possible values of reservoir storage volumes was found. The other work referred to in this paper is a paper by Marton et al. (2014) describing the calculation of reservoir storage capacity in the conditions of measurement uncertainties and extended to using the AR and ARMA models, generators of artificial streamflow series of mean monthly discharges. Random discharge series, in this case as data inputs for artificial streamflow series generators, were used, resulting in random samples of artificial streamflow series. These random series were evaluated using a reservoir simulation model. The calculation result was a spectrum of reservoir storage capacities for maximum reliability of 100%, which was statistically evaluated. Both papers have indicated that the current water volumes in reservoirs can be underestimated and, in dry periods, may result in an unexpected failure in surface water supply.

As regards current knowledge, uncertainty can be derived from set theory, but also uncertainty can be derived using statistics. From set theory, it is necessary to mention the application of uncertainty based on the theory of fuzzy sets (Zadeh, 1965) and the theory of possibilities (Klir, 2005). However, the first definition of uncertainty was by Knight (1921), nowadays known as Knightian uncertainty. The uncertainty concept is currently viewed from different aspects, with plenty of definitions and points of view, such as the uncertainty associated with the definition of risk, uncertainties applied in forecasting problems, and also the uncertainty of measurement. Uncertainties
applied in hydrology were described, for example, by Beven and Binley (1992). They described in detail a method called GLUE – generalized likelihood uncertainty estimation. This was followed by numerous publications which deal with this issue, such as Beven (2007). Uncertainties in measurement were first formulated on the basis of the WECC (1990) agreement. A statistical approach using the concept of uncertainty of measurement, which clearly defined the introduction and calculation of measurement uncertainties, was introduced as the “Guide to Expression of Uncertainty in Measurement” (GUM 1993). The ISO GUIDE 99998 Standard (2004) deals with the distribution and propagation of uncertainties using Monte Carlo simulation. Hydrological applications, including propagation of uncertainties into hydrological inputs when measuring precipitation, water inflows into reservoirs and evaporation in the water balances of reservoirs, were dealt with by Winter (1981). LaBaugh and Winter (1984) examined the influence of uncertainties in the measurements of water inflow into reservoirs, water outflows from reservoirs and evaporation, and other hydrological and operating parameters on the volume and chemical analysis of water in reservoirs. Coxon et al. (2015) examine the risks and uncertainties in, and influence on reservoir storage using Monte Carlo simulations. Kuria and Vogel (2014) carried out an analysis of uncertainties in reservoir storage using the water supply yield model. The aim of the paper is to present another possible application of the Monte Carlo method for introducing uncertainties into the hydrological, morphological and operating input data required for reservoir storage capacity design, which is crucial in low-water periods. This is also connected with the calculation of reliability for water outflows from the reservoir in adaptive conditions. Input hydrological, morphological and operating data for the solution are considered, especially water inflow into the reservoir, water losses from the reservoir by evaporation from the water surface and by dam seepage, the reservoir elevation–volume curve and the reservoir elevation–area curve. A reservoir storage model was created for this purpose using a single-pass simulation method to determine reliability for water outflows from the reservoir, both considering water losses from the reservoir and ignoring such losses. By introducing uncertainty into the input data, the Monte Carlo method is used to determine, by repeated solutions, the spectrum of reliability of reservoir storage capacity. This is then evaluated and appropriately interpreted. As the uncertainties in the input data are unknown, the work focuses on compiling sensitivity analysis between the uncertainty in the input data of a solution for the storage capacity of the reservoir and the uncertainty of the achieved reliability of controlled water outflows from the reservoir.

METHOD

Monte Carlo method

The general procedure for generating uncertainty affected hydrological, morphological and operating input data for the related water management analysis of a reservoir for its storage capacity is as follows. Uncertainties of input quantities are introduced into the calculations using the Monte Carlo method. Using the distribution curve $F(X)$, a random position of values $N_X$ within the interval of a given uncertainty are generated as input value $X_i$. Value $X_i$ is considered random and independent of values $X_{i-1}$ and $X_{i+1}$. This presumption will allow the introduction of the normal probability distribution $N(\mu(X), \sigma(X))$. Then, each input value $X_i$ is considered as a mean value $\mu(X)$ and the amount of uncertainty is defined as the standard deviation $\sigma(X)$. Subsequently, a cumulative distribution function $F(X)$ of normal standardized probability distribution is generated for each mean value $\mu(X)$. The pseudorandom number generator generates a random number from an interval in which random quantity value $N_X$ is generated.

Fig. 1. Principle of generating uncertainties in input elements using the Monte Carlo method.
The basic principle of generating random positions of points in the two-dimensional coordinate system \((NX, NY)\) is identical to the theory described above. The dissimilarity is given by plotting a point which requires plotting two Monte Carlo generators independent of each other. Each generator produces a random position of point \(NX\) (e.g. water level elevation \(NH_l\)) and with it a random value \(NY\) (water volume in reservoir \(NF\)). The result on the reservoir elevation–volume curve is then a random point coordinate \((NY, NH)\) of the reservoir elevation–volume curve. See Fig. 1.

As observed, the reservoir inflow, water surface evaporation, dam seepage and reservoir elevation–area and elevation–volume curves are considered to be hydrological and operating inputs. The principle of introducing uncertainties into the calculation of reservoir storage capacity is shown in Fig. 2.

The generated random curves of water inflows into the reservoir, water evaporation from the water surface, seepages and random area and elevation–volume curves serve as input values for a simulation model which, using single-pass simulation, simulates the behaviour of the reservoir in the conditions of data affected with uncertainty.

Reservoir simulation model and reservoir performance calculation

The basis for a reservoir simulation model is an adjusted equation in the cumulative form converted to the following inequalities (1) Starý (2005).

\[
0 \leq \sum_{i=0}^{k} (O_i - Q_i) \Delta t + (O_{i+1} - Q_{i+1}) \Delta t \leq V_{Z,max} \tag{1}
\]

where \(O_i\) is the reservoir outflow, \(Q_i\) the reservoir inflow for \(i = 1, \ldots, n\), and \(\Delta t\) is the time step of calculation (one month). \(O_{i+1}\) is the outflow from the reservoir in the following time step, where in step \(i+1\) the value of \(O_{i+1}\) is replaced with the value of the required outflow \(O_p\). The time course of the numbered sum simulates the course of emptying the reservoir storage by time steps \(i = 1, \ldots, k\). For \(i = 0\) it is necessary to enter the starting solution condition after the sum value. Inequality (1) is limited from both the left and the right. From the left it is limited by value 0 (full storage capacity) and from the right by value \(V_{z, max}\) (empty storage capacity) characterizing the reservoir storage capacity available for the reservoir. By calculating the value of the expression, the current emptying of the storage volume \(V_{z,i+1}\) is obtained and it is then tested as to whether it lies in a particular interval \((0, V_{z, max})\). If not, it is necessary to find value \(O_p\) (for the sum of the expression to be equal to zero, idle discharge will occur, or if equal to \(V_{z, max}\) – a failure will occur).

The general definition of reliability was successively described by (Hashimoto et al., 1982; Klemš, 1967; Kritskiy and Menkel, 1952). The classification of a failure in the reservoir storage capacity for the following calculation of reliability is as follows (2).

\[
Z_{t,i} = \begin{cases} 1, & O_i \geq O_p \\ 0, & O_i < O_p \end{cases}
\]

\(Z_{t,i}\) describes the reservoir storage capacity in a no failure situation (satisfactory state), \(Z_{t,i} = 0\) describes the reservoir storage capacity in a failure situation (unsatisfactory state). The required reliability can be further calculated from values \(Z_{t,i}\). Generally, reliability is calculated by time-based reliability as temporal reliability and occurrence reliability, and volumetric reliability is calculated separately. The paper uses the formula for the calculation of temporal reliability \(P_T\) (3).

\[
P_T = \frac{1}{k} \sum_{i=1}^{k} Z_{t,i}
\]

where \(k\) is the number of months in the period being solved.

PRACTICAL APPLICATION

The model was applied in practice to the existing reservoir, Vír I, which is situated in the Vysočina Region, Czech Republic. This is a multi-use reservoir serving mainly as flood protection and surface water accumulation for water supply and hydroelectric purposes. The reservoir is built in the Svatka River basin and has been in operation since 1957. The Svatka is the main inflow into the reservoir. The mean long-term inflow into the reservoir \(Q_p\) is 3.34 m³ s⁻¹. Input values for the calculation were made up of a time series of mean monthly flows over 60 years with the measurement period from 1950 to 2010. The mean annual evaporation from the water surface \(E_{ANNUAL} = 613\) mm. The monthly evaporation values from water surface were derived in a simplified manner according to the percentage distribution of evaporation according to the CSN 75 2405 Standard (2004) and from the mean annual evaporation values for Vír I reservoir, see Table 1.

Fig. 3. Relation between required outflow O_p and temporal reliability P_T without considering water losses from the reservoir.

The total reservoir volume is V_TOTAL 56.193 x 10⁶ m³, active storage volume V_Z,max is 44.056 x 10⁶ m³ and flood reservoir volume V_FLOOD is 8.337 x 10⁶ m³. The total dam height is 67.3 m. The ecological flow from the reservoir Q_ECO is 0.53 m³ s⁻¹. The value of seepage through the dam was derived from empirical observation and for the gravity concrete dam it is 0.15 l s⁻¹ per 1000 m².

The calculation of temporal reliability P_T for an increased outflow from the reservoir was analysed with and without considering water losses from the reservoir. When water losses were considered in the calculations of temporal reliability, the described procedures for generating uncertainty-affected hydrological, morphological and operating inputs were applied. The analysis was carried out for the values of increased required outflow O_p lying in the interval O_p(2.1; 3.0) m³ s⁻¹. The selected number of repetitions using the Monte Carlo method was 300. Input uncertainties for the analysis ranged in intervals ±3, ±6, ±9, and ±15%. The algorithm simulating the behaviour of the reservoir then calculated random discharges N_0i of water from the reservoir and temporal reliability of N_P_i. Then, random courses of monthly filling and emptying of the reservoir storage capacity were calculated. For a better presentation of the results, these values were evaluated statistically. The mean value μ(X) for each random set is considered to be the resultant value and the standard deviation σ(X) is considered to be the standard uncertainty related to a particular result. The total, extended uncertainty, type "U_{a,ε}" covering almost 100% or specifically 99.97% of occurrences of the monitored quantity, corresponded to value μ(X)±3σ. Sensitivity analysis was carried out for the calculation without considering water losses from the reservoir, when only
inflow into the reservoir was burdened with uncertainty, see Table 2 and Fig. 3. Calculations were also made while considering water losses from the reservoir. First, only the evaporation values, elevation–volume curve, elevation–area curve and seepage through the dam were affected with uncertainty, see Table 3 and Fig. 4. Then, reservoir inflow, evaporation, elevation–volume curve, elevation–area curve and seepage through the dam were affected with uncertainty, see Table 4 and Fig. 5.

The shape of the curves in Figs. 3, 4, and 5 in the range from \( Q_p = 2.3 \text{ m}^3\text{s}^{-1} \) to \( Q_p = 2.5 \text{ m}^3\text{s}^{-1} \) is caused by a large time step in the calculations (1 month), and also by a step increase in the number of failure months, which is a small number in the given Table 3. Calculation with considering water losses from reservoir. Uncertainties considered for evaporation, elevation-volume (area) curves and seepage through dam body combinations.

**Table 3.** Calculation with considering water losses from reservoir. Uncertainties considered for evaporation, elevation-volume (area) curves and seepage through dam body combinations.

Fig. 5. Relation between required outflow $Q_o$ and temporal reliability $P_t$, with considering water losses from reservoir for input uncertainties $\pm 3$, $\pm 6$, $\pm 9$ $\pm 15\%$ and an inflow, evaporation, elevation-volume(area) curves and dam seepage combination.

Fig. 6. The course of filling reservoir storage capacity in the conditions of entered input data uncertainties $U_i = \pm 3\%$ a $\pm 15\%$ for the selected low water period.
range of required outflow from the reservoir $O_r$. For values $O_r = 2.6 \text{ m}^3 \text{ s}^{-1}$ and higher, there is an apparent increase in the failure months, due to which the curves are smooth. The more significant interval of spacing in the curves in Fig. 5, unlike Figs. 3 and 4, in the field of required outflow from the reservoir $O_r = 2.2 \text{ m}^3 \text{ s}^{-1}$ is caused by the number of failure months occurring in the evaluated set. The process contingency applied when uncertainties are introduced into all input data of the solution results in a significant increase in the number of failure months compared to the solution in which only uncertainties of reservoir inflow or uncertainties for evaporation, elevation–volume (–area) curves and seepage through the dam combination are applied. The analysis also included values of filling the reservoir storage capacity. Fig. 6 then shows the course of filling the reservoir for a particular number of repetitions and for the selected low water period.

**SUMMARY**

The final comparison is from selected required outflow from the reservoir $O_r = 2.5$ and $O_r = 3.0 \text{ m}^3 \text{ s}^{-1}$, where the influence is clearly graded. In the variant without applying water losses from the reservoir, the temporal reliability for $O_r = 2.5 \text{ m}^3 \text{ s}^{-1}$ is in interval $P_r \in (98.906\%\;\text{-}\;98.908\%)$, i.e. $P_r = 98.907\% \pm 0.001\%$ for input uncertainty $\pm 3\%$ and in interval $P_r \in (98.857\%\;\text{-}\;99.129\%)$ $P_r = 98.852\% \pm 0.277\%$ for input uncertainty $\pm 15\%$. The interval of temporal reliability for the $O_r = 3.0 \text{ m}^3 \text{ s}^{-1}$ range in interval $P_r \in (90.511\%\;\text{-}\;91.187\%)$ is $P_r = 90.849\% \pm 0.338\%$ for input uncertainty $3\%$ and in interval $P_r \in (90.097\%\;\text{-}\;92.071\%)$ $P_r = 91.084\% \pm 0.987\%$ for input uncertainty $15\%$. In the variant without applying all combinations, i.e. considering uncertainties in both inflow and water losses from the reservoir, the interval of temporal reliability was in $P_r \in (98.663\%\;\text{-}\;99.055\%)$ $P_r = 98.859\% \pm 0.196\%$ for input uncertainty $\pm 3\%$ and for uncertainty $\pm 15\%$ in interval $P_r \in (98.27\%\;\text{-}\;99.172\%)$ $P_r = 98.721\% \pm 0.451\%$. For $O_r = 3.0 \text{ m}^3 \text{ s}^{-1}$ the interval of temporal reliability acquired values $P_r \in (90.154\%\;\text{-}\;90.958\%)$ $P_r = 90.556\% \pm 0.402\%$ for input uncertainty $3\%$ and $P_r \in (89.57\%\;\text{-}\;91.646\%)$ $P_r = 90.608\% \pm 1.038\%$ for input uncertainty $15\%$. The above mentioned results show a logical conclusion that with increasing input data uncertainty, the uncertainty in temporal reliability also increases. Converted to the number of failure months, increased discharge $O_r = 2.5 \text{ m}^3 \text{ s}^{-1}$ in the solution without considering uncertainties and with considering reservoir water losses, corresponds to eight failure months, and for $O_r = 3.0 \text{ m}^3 \text{ s}^{-1}$ to 70 months. When considering input uncertainties $\pm 3\%$, the number of failure months is from 8 to 9 months for $O_r = 2.5 \text{ m}^3 \text{ s}^{-1}$ and 66 to 72 months for $O_r = 3.0 \text{ m}^3 \text{ s}^{-1}$. For the input data uncertainty of $\pm 15\%$, the number of possible failure months is 8 to 12 for $O_r = 2.5 \text{ m}^3 \text{ s}^{-1}$ and 60 to 76 months for $O_r = 3.0 \text{ m}^3 \text{ s}^{-1}$. The presented results show how uncertainties can influence the increase in failure months and which intervals the temporal reliability can then acquire.

**CONCLUSIONS**

In the manipulation rules for the Vir I reservoir, the stated temporal reliability for the hydrological period 1931 to 1991 is $P_r = 99.59\%$ for a required reservoir outflow $O_r = 2.5 \text{ m}^3 \text{ s}^{-1}$. This means that the current state is underestimated by approximately 1% compared to the calculations which were undertaken for that reservoir. Underestimation can be explained by the length of the input streamflow series introduced to the calcula-
